#### Abstract

We introduce *orbital branching*, an effective branching method for integer programs containing a great deal of symmetry. The method is based on computing groups of variables that are equivalent with respect to the symmetry remaining in the problem after branching, including symmetry which is not present at the root node. These groups of equivalent variables, called orbits, are used to create a valid partitioning of the feasible region which significantly reduces the effects of symmetry while still allowing a flexible branching rule. We also show how to exploit the symmetries present in the problem to fix variables throughout the branch-and-bound tree.

Orbital branching can easily be incorporated into standard IP software. Through an empirical study on a test suite of symmetric integer programs, the question as to the most effective orbit on which to base the branching decision is investigated. The resulting method is shown to be quite competitive with a similar method known as *isomorphism pruning* and significantly better than a state-of-the-art commercial solver on symmetric integer programs.

Keywords: Integer programming; branch-and-bound algorithms.

### 1 Introduction

In this work, we focus on packing and covering integer programs (IP)s of the form

$$\max_{x \in \{0,1\}^n} \{e^T x \mid Ax \le e\} \text{ and}$$
 (PIP)

$$\min_{x \in \{0,1\}^n} \{ e^T x \mid Ax \ge e \},\tag{CIP}$$

where  $A \in \{0,1\}^{m \times n}$ , and e is a vector of ones of conformal size. Our particular focus is on cases when (CIP) or (PIP) is highly-symmetric, a concept we formalize as follows. Let  $\Pi^n$  be the set of all permutations of  $I^n = \{1, \ldots, n\}$ . Given a permutation  $\pi \in \Pi^n$  and a permutation  $\sigma \in \Pi^m$ , let  $A(\pi, \sigma)$  be the matrix obtained by permuting the columns of A by  $\pi$  and the rows of A by  $\sigma$ , i.e.  $A(\pi, \sigma) = P_{\sigma}AP_{\pi}$ , where  $P_{\sigma}$  and  $P_{\pi}$  are permutation matrices. The symmetry group G of the matrix A is the set of permutations

$$\mathcal{G}(A) \stackrel{\text{def}}{=} \{ \pi \in \Pi^n \mid \exists \sigma \in \Pi^m \text{ such that } A(\pi, \sigma) = A \}.$$

So, for any  $\pi \in \mathcal{G}(A)$ , if  $\hat{x}$  is feasible for (CIP) or (PIP) (or the LP relaxations of (CIP) or (PIP)), then if the permutation  $\pi$  is applied to the coordinates of  $\hat{x}$ , the resulting solution, which we denote as  $\pi(\hat{x})$ , is also feasible. Moreover, the solutions  $\hat{x}$  and  $\pi(\hat{x})$  have equal objective value.

This equivalence of solutions induced by symmetry is a major factor that might confound the branch-and-bound process. For example, suppose  $\hat{x}$  is a (non-integral) solution to an LP relaxation of PIP or CIP, with  $0 < \hat{x}_j < 1$ , and the decision is made to branch down on variable  $x_j$  by fixing  $x_j = 0$ . If  $\exists \pi \in \mathcal{G}(A)$  such that  $[\pi(\hat{x})]_j = 0$ , then  $\pi(\hat{x})$  is a feasible solution for this child node, and  $e^T\hat{x} = e^T(\pi(\hat{x}))$ , so the relaxation value for the child node will not change. If the cardinality of  $\mathcal{G}(A)$  is large, then there are many permutations through which the parent solution of the relaxation can be preserved in this manner, resulting in many branches that do not change the bound on the parent node. Symmetry has long been recognized as a curse for solving integer programs, and auxiliary (often extended) formulations are often sought that reduce the amount of symmetry in an IP formulation [1, 7, 14]. In addition, there is a body of research on valid inequalities that can help exclude symmetric feasible solutions [9, 17, 18].

A different idea, isomorphism pruning, introduced by Margot [10, 11] in the context of IP and dating back to Bazaraa and Kirca [2], examines the symmetry group of the problem in order to prune isomorphic subproblems of the enumeration tree. The branching method introduced in this work, orbital branching, also uses the symmetry group of the problem. However, instead of examining this group to ensure that an isomorphic node will never be evaluated, the group is used to guide the branching decision. At the cost of potentially evaluating isomorphic subproblems, orbital branching allows for considerably more flexibility in the choice of branching entity than isomorphism pruning. Furthermore, orbital branching can be easily incorporated within a standard MIP solver and even exploit problem symmetry that may only be locally present at a nodal subproblem.

The remainder of the paper is divided into five sections. In §2 we give some mathematical preliminaries. Orbital branching is introduced and formalized in §3, and a mechanism to fix additional variables based on symmetry considerations called *orbital fixing* is described there. A more complete comparison to isomorphism pruning is also presented in §3. Implementation details are provided in §4, and computational results are presented in §5. Conclusions about the impact of orbital branching and future research directions are given in §6.

### 2 Preliminaries

Orbital branching is based on elementary concepts from algebra that we recall in this section to make the presentation self-contained. Some definitions are made in terms of an arbitrary permutation group  $\Gamma$ , but for concreteness, the reader may consider the group  $\Gamma$  to be the symmetry group of the matrix  $\mathcal{G}(A)$ .

For a set  $S \subseteq I^n$ , the *orbit* of S with respect to  $\Gamma$  is the set of all subsets of  $I^n$  to which S can be sent by permutations in  $\Gamma$ , i.e.,

$$\operatorname{orb}(S,\Gamma) \stackrel{\mathrm{def}}{=} \{ S' \subseteq I^n \mid \exists \pi \in \Gamma \text{ such that } S' = \pi(S) \}.$$

In the orbital branching we are concerned with the orbits of sets of cardinality one, corresponding to decision variables  $x_j$  in PIP or CIP. By definition, if  $j \in \text{orb}(\{k\}, \Gamma)$ , then  $k \in \text{orb}(\{j\}, \Gamma)$ , i.e. the variable  $x_j$  and  $x_k$  share the same orbit. Therefore, the union of the orbits

$$\mathcal{O}(\Gamma) \stackrel{\mathrm{def}}{=} \bigcup_{j=1}^{n} \mathrm{orb}(\{j\}, \Gamma)$$

forms a partition of  $I^n = \{1, 2, ..., n\}$ , which we refer to as the orbital partition of  $\Gamma$ , or simply the *orbits* of  $\Gamma$ . The orbits encode which variables are "equivalent" with respect to the symmetry  $\Gamma$ .

The stabilizer of a set  $S \subseteq I^n$  in  $\Gamma$  is the set of permutations in  $\Gamma$  that send S to itself.

$$stab(S, \Gamma) = \{ \pi \in \Gamma \mid \pi(S) = S \}.$$

The stabilizer of S is a subgroup of  $\Gamma$ .

We characterize a node  $a=(F_1^a,F_0^a)$  of the branch-and-bound enumeration tree by the indices of variables fixed to one  $F_1^a$  and fixed to zero  $F_0^a$  at node a. The set of free variables at node a is denoted by  $N^a=I^n\setminus F_0^a\setminus F_1^a$ . At node a, the set of feasible solutions to (CIP) or (PIP) is denoted by  $\mathcal{F}(a)$ , and the value of an optimal solution for the subtree rooted at node a is denoted is  $z^*(a)$ .

### 3 Orbital Branching

In this section we introduce orbital branching, an intuitive way to exploit the orbits of the symmetry group  $\mathcal{G}(A)$  when making branching decisions. The classical 0-1 branching variable dichotomy does not take advantage of the problem information encoded in the symmetry group. To take advantage of this information in orbital branching, instead of branching on individual variables, orbits of variables are used to create the branching dichotomy. Informally, suppose that at the current subproblem there is an orbit of cardinality k in the orbital partitioning. In orbital branching, the current subproblem is divided into k+1 subproblems: the first k subproblems are obtained by fixing to one in turn each variable in the orbit while the  $(k+1)^{\text{St}}$  subproblem is obtained by fixing all variables in the orbit to zero. For any pair of variables  $x_i$  and  $x_j$  in the same orbit, the subproblem created when  $x_i$  is fixed to one is essentially equivalent to the subproblem created when  $x_j$  is fixed to one. Therefore, we can keep in the subproblem list only *one* representative subproblem, pruning the (k-1) equivalent subproblems. This is formalized below.

Let  $A(F_1^a, F_0^a)$  be the matrix obtained by removing from the constraint matrix A all columns in  $F_0^a \cup F_1^a$  and either all rows intersecting columns in  $F_1^a$  (CIP case) or all columns nonorthogonal to columns in  $F_1^a$  (PIP case). Note that if  $x \in \mathcal{F}(a)$  and x is feasible with respect to the matrix A, then x is feasible with respect to the matrix  $A(F_1^a, F_0^a)$ .

Let  $O = \{i_1, i_2, \dots, i_{|O|}\} \subseteq N^a$  be an orbit of the symmetry group  $\mathcal{G}(A(F_1^a, F_0^a))$ . Given a subproblem a, the disjunction

$$x_{i_1} = 1 \lor x_{i_2} = 1 \lor \dots x_{i_O} = 1 \lor \sum_{i \in O} x_i = 0$$
 (1)

induces a feasible partition of the search space. In what follows, we show that for any two variables  $x_j, x_k \in O$ , the two children a(j) and a(k) of a, obtained by fixing respectively  $x_j$  and  $x_k$  to 1 have the same optimal solution value. As a consequence, disjunction (1) can be replaced by the binary disjunction

$$x_h = 1 \lor \sum_{i \in O} x_i = 0, \tag{2}$$

where h is a variable in O. Formally, we have Theorem 1.

**Theorem 1** Let O be an orbit in the orbital partitioning  $\mathcal{O}(\mathcal{G}(A(F_1^a, F_0^a)))$ , and let j, k be two variable indices in O. If  $a(j) = (F_1^a \cup \{j\}, F_0^a)$  and  $a(k) = (F_1^a \cup \{k\}, F_0^a)$  are the child nodes created when branching on variables  $x_j$  and  $x_k$ , then  $z^*(a(j)) = z^*(a(k))$ .

**Proof.** Let  $x^*$  be an optimal solution of a(j) with value  $z^*(a(j))$ . Obviously  $x^*$  is also feasible for a. Since j and k are in the same orbit O, there exists a permutation  $\pi \in \mathcal{G}(A(F_1^a, F_0^a))$  such that  $\pi(j) = k$ . By definition,  $\pi(x^*)$  is a feasible solution of a with value  $z^*(a(j))$  such that  $x_k = 1$ . Therefore,  $\pi(x^*)$  is feasible for a(k), and  $z^*(a(k)) = z^*(a(j))$ .

The basic orbital branching method is formalized in Algorithm 1.

### Algorithm 1 Orbital Branching

**Input:** Subproblem  $a = (F_1^a, F_0^a)$ , non-integral solution  $\hat{x}$ .

Output: Two child subproblems b and c.

Step 1. Compute orbital partition  $\mathcal{O}(\mathcal{G}(A(F_1^a, F_0^a))) = \{O_1, O_2, \dots, O_p\}.$ 

**Step 2.** Select orbit  $O_{j^*}, j^* \in \{1, 2, ..., p\}$ .

Step 3. Choose arbitrary  $k \in O_{j^*}$ . Return subproblems  $b = (F_1^a \cup \{k\}, F_0^a)$  and  $c = (F_1^a, F_0^a \cup O_{j^*})$ .

The consequence of Theorem 1 is that the search space is limited, but orbital branching has also the relevant effect of reducing the likelihood of encountering symmetric solutions. Namely, no solutions in the left and right child nodes of the current node will be symmetric with respect to the local symmetry. This is formalized in Theorem 2.

**Theorem 2** Let b and c be any two subproblems in the enumeration tree. Let a be the first common ancestor of b and c. There  $\not\exists x \in \mathcal{F}(b)$  such that  $\exists \pi \in \mathcal{G}(A(F_0^a, F_1^a))$  with  $\pi(x) \in \mathcal{F}(c)$ .

**Proof.** Suppose not, i.e., that there  $\exists x \in \mathcal{F}(b)$  and a permutation  $\pi \in \mathcal{G}(A(F_0^a, F_1^a))$  such that  $\pi(x) \in \mathcal{F}(c)$ . Let  $O_i \in \mathcal{O}(\mathcal{G}(A(F_1^a, F_0^a)))$  be the orbit chosen to branch on at subproblem a. W.l.o.g. we can assume  $x_k = 1$  for some  $k \in O_i$ . We have that  $x_k = [\pi(x)]_{\pi(k)} = 1$ , but  $pi(k) \in O_i$ . Therefore, by the orbital branching dichotomy,  $\pi(k) \in F_0^c$ , so  $\pi(x) \notin \mathcal{F}(c)$ .

Note that by using the matrix  $A(F_1^a, F_0^a)$ , orbital branching attempts to use symmetry found at all nodes in the enumeration tree, not just the symmetry found at the root node. This makes it possible to prune nodes whose corresponding solutions are not symmetric in the original IP.

#### 3.1 Orbital Fixing

In orbital branching, all variables fixed to zero and one are removed from the constraint matrix at every node in the enumeration tree. As Theorem 2 demonstrates, using orbital branching in this way ensures that any two nodes are not equivalent with respect to the symmetry found at their first common ancestor. It is possible however, for two child subproblems to be equivalent with respect to a symmetry group found elsewhere in the tree. In order to combat this type of symmetry we perform *orbital fixing*, which works as follows.

Consider the symmetry group  $\mathcal{G}(A(F_1^a,\emptyset))$  at node a. If there exists an orbit O in the orbital partition  $\mathcal{O}(\mathcal{G}(A(F_1^a,\emptyset)))$  that contains variables such that  $O\cap F_0^a\neq\emptyset$  and  $O\cap N^a\neq\emptyset$ , then all variables in O can be fixed to zero. In the following theorem, we show that such variable setting (orbital fixing) excludes feasible solutions only if there exists a feasible solution of the same objective value to the left of the current node in the branch and bound tree. (We assume that the enumeration tree is oriented so that the branch with an additional variable fixed at one is the left branch).

To aid in our development, we introduce the concept of a focus node. For  $x \in \mathcal{F}(a)$ , we call node b(a, x) a focus node of a with respect to x if  $\exists y \in \mathcal{F}(b)$  such that  $e^T x = e^T y$  and b is found to the left of a in the tree.

**Theorem 3** Let  $\{O_1, O_2, \dots O_q\}$  be an orbital partitioning of  $\mathcal{G}(A(F_1^a, \emptyset))$  at node a, and let the set

$$S \stackrel{\text{def}}{=} \{j \in N^a \mid \exists k \in F_0^a \text{ and } (j \cap k) \in O_\ell \text{ for some } \ell \in \{1, 2, \dots q\}\}$$

be the set of free variables that share an orbit with a variable fixed to zero at a. If  $x \in \mathcal{F}(a)$  with  $x_i = 1$  for some  $i \in S$ , then there exists a focus node for a with respect to x.

**Proof:** Suppose that a is the first node in any enumeration tree where S is nonempty. Then, there exist  $j \in F_0^a$  and  $i \in S$  such that  $i \in \operatorname{orb}(j, \mathcal{G}(A(F_1^a, \emptyset)))$ , i.e., there exists a  $\pi \in \mathcal{G}(A(F_1^a, \emptyset))$  with  $\pi(i) = j$ . W.l.o.g., suppose that j is any of the first such variables fixed to zero on the path from the root node to a and let c be the subproblem in which such a fixing occurs. Let  $\rho(c)$  be the parent node of c. By our choice of j as the first fixed variable,  $\{\pi(i)|i\in F_0^a-F_0^\rho\}\cap F_0^{\rho(c)}=\emptyset$ . Therefore,  $\pi(x)$  is not feasible in a since it does not satisfy the bounds, but is feasible in  $\rho(c)$  and has the same objective value of x. Since j was fixed by orbital branching then the left child of  $\rho(c)$  has  $x_h=1$  for some  $h\in\operatorname{orb}(j,\mathcal{G}(A(F_1^{\rho(c)},F_0^{\rho(c)}F_1^{\rho(c)}))$ . Let  $\pi'\in\operatorname{orb}(j,\mathcal{G}(A(F_1^{\rho(c)},F_0^{\rho(c)}F_1^{\rho(c)}))$  have  $\pi'(j)=h$ . Then  $\pi'(\pi(x))$  is feasible in the left node with the same objective value of x. The left child node of  $\rho(c)$  is then the focus node of a with respect to x.

If a is not a first node in the enumeration tree one can apply the same argument to the first ancestor b of a such that  $S \neq \emptyset$ . The focus node of c = (b, x) is then a focus node of (a, x).

An immediate consequence of Theorem 3 is that for all  $i \in F_0^a$  and for all  $j \in \text{orb}(i, \mathcal{G}(A(F_1^a, \emptyset)))$  one can set  $x_i = 0$ . We update orbital branching to include orbital fixing in Algorithm 2.

In orbital fixing, the set S of additional variables set to zero is a function of  $F_0^a$ . Variables may appear in  $F_0^a$  due to a branching decision or due to traditional methods for variable fixing in integer programming, e.g. reduced cost fixing or implication-based fixing. Orbital fixing, then, gives a way to *enhance* traditional variable-fixing methods by including the symmetry present at a node of the branch and bound tree.

#### 3.2 Comparison to Isomorphism Pruning

The fundamental idea behind isomorphism pruning is that for each node  $a=(F_1^a,F_0^a)$ , the orbits  $\operatorname{orb}(F_1^a,\mathcal{G}(A))$  of the "equivalent" sets of variables to  $F_1^a$  are computed. If there is a node  $b=(F_1^b,F_0^b)$  elsewhere in the enumeration tree such that  $F_1^b\in\operatorname{orb}(F_1^a,\mathcal{G}(A))$ , then the node a need not be evaluated—the node a is pruned by isomorphism. A very distinct and powerful advantage of this method is that no nodes whose

| Algorithm 2 Orbital Branching with Orbital Fixing |  |  |  |  |  |
|---|--|--|--|--|--|
| Input:<br>Output:                                 | Subproblem $a = (F_1^a, F_0^a)$ (with free variables $N^a = I^n \setminus F_1^a \setminus F_0^a$ ), fractional solution $\hat{x}$ . Two child nodes $b$ and $c$ .  |  |  |  |  |
| Step 1.   | Compute orbital partition $\mathcal{O}(\mathcal{G}(A(F_1^a,\emptyset))) = \{\hat{O}_1,\hat{O}_2,\ldots,\hat{O}_q\}$ . Let $S \stackrel{\text{def}}{=} \{j \in N^a \mid \exists k \in F_0^a \text{ and } (j \cap k) \in O_\ell \text{ for some } \ell \in \{1,2,\ldots q\}\}$ . |  |  |  |  |
| Step 2.   | Compute orbital partition $\mathcal{O}(\mathcal{G}(A(F_1^a, F_0^a))) = \{O_1, O_2, \dots, O_p\}.$  |  |  |  |  |
| Step 3.   | Select orbit $O_{j^*}, j^* \in \{1, 2,, p\}$ .   |  |  |  |  |
| Step 4.   | Choose arbitrary $k \in O_{j^*}$ . Return child subproblems $b = (F_1^a \cup \{k\}, F_0^a \cup S)$ and $c = (F_1^a, F_0^a \cup O_{j^*} \cup S)$ .  |  |  |  |  |

sets of fixed variables are isomorphic will be evaluated. One disadvantage of this method is that computing  $\operatorname{orb}(F_1^a,\mathcal{G}(A))$  can require computational effort on the order of  $O(n|F_1^a|!)$ . A more significant disadvantage of isomorphism pruning is that  $\operatorname{orb}(F_1^a,\mathcal{G}(A))$  may contain many equivalent subsets to  $F_1^a$ , and the entire enumeration tree must be compared against this list to ensure that a is not isomorphic to any other node b. In a series of papers, Margot offers a way around this second disadvantage [10, 11]. The key idea introduced is to declare one *unique representative* among the members of  $\operatorname{orb}(F_1^a,\mathcal{G}(A))$ , and if  $F_1^a$  is not the unique representative, then the node a may safely be pruned. The advantage of this extension is that it is trivial to check whether or not node a may be pruned once the orbits  $\operatorname{orb}(F_1^a,\mathcal{G}(A))$  are computed. The disadvantage of the method is ensuring that the unique representative occurs *somewhere* in the branch and bound tree requires a relatively inflexible branching rule. Namely, *all* child nodes at a fixed depth must be created by branching on the *same* variable.

Orbital branching does not suffer from this inflexibility. By not focusing on pruning *all* isomorphic nodes, but rather eliminating the symmetry through branching, orbital branching offers a great deal more flexibility in the choice of branching entity. Another advantage of orbital branching is that by using the symmetry group  $\mathcal{G}(A(F_1^a, F_0^a))$ , symmetry *introduced* as a result of the branching process is also exploited.

Both methods allow for the use of traditional integer programming methodologies such as cutting planes and fixing variables based on considerations such as reduced costs and implications derived from preprocessing. In isomorphism pruning, for a variable fixing to be valid, it must be that *all* non-isomorphic optimal solutions are in agreement with the fixing. Orbital branching does not suffer from this limitation. A powerful idea in both methods is to combine the variable fixing with symmetry considerations in order to fix many additional variables. This idea is called *orbit setting* in [11] and *orbital fixing* in this work (see §3.1).

### 4 Implementation

The orbital branching method has been implemented using the user application functions of MINTO v3.1 [16]. The branching dichotomy of Algorithm 1 or 2 is implemented in the appl\_divide() method, and reduced cost fixing is implemented in appl\_bounds(). The entire implementation, including code for all the branching rules subsequently introduced in §4.2 consists of slightly over 1000 lines of code. All advanced IP features of MINTO were used, including clique inequalities, which can be useful for instances of (PIP).

### **4.1** Computing $G(\cdot)$

Computation of the symmetry groups required for orbital branching and orbital fixing is done by computing the automorphism group of a related graph. Recall that the automorphism group  $\operatorname{Aut}(G(V,E))$  of a graph

G = (V, E), is the set of permutations of V that leave the incidence matrix of G unchanged, i.e.

$$\operatorname{Aut}(G(V,E)) = \{ \pi \in \Pi^{|V|} \mid (i,j) \in E \Leftrightarrow (\pi(i),\pi(j)) \in E \}.$$

The matrix A whose symmetry group is to be computed is transformed into a bipartite graph G(A) = (N, M, E) where vertex set  $N = \{1, 2, \ldots, n\}$  represents the variables, and vertex set  $M = \{1, 2, \ldots, m\}$  represents the constraints. The edge  $(i, j) \in E$  if and only if  $a_{ij} = 1$ . Under this construction, feasible solutions to (PIP) are subsets of the vertices  $S \subseteq N$  such that each vertex  $i \in M$  is adjacent to at most one vertex  $j \in S$ . In this case, we say that S packs M. Feasible solutions to (CIP) correspond to subsets of vertices  $S \subseteq N$  such that each vertex  $i \in M$  is adjacent to at least one vertex  $j \in S$ , or S covers M. Since applying members of the automorphism group preserves the incidence structure of a graph, if S packs (covers) M, and  $\pi \in \operatorname{stab}(M, \operatorname{Aut}(G(A)))$ , then there exists a  $\sigma$  where  $\pi(S)$  packs (covers)  $\sigma(M) = M$ . This implies that if  $\pi \in \operatorname{stab}(M, \operatorname{Aut}(G(A)))$ , then the restriction of  $\pi$  to N must be an element of G(A), i.e. using the graph G(A), one can find elements of symmetry group G(A). In particular, we compute the orbital partition of the stabilizer of the constraint vertices M in the automorphism group of G(A), i.e.

$$\mathcal{O}(\operatorname{stab}(M,\operatorname{Aut}(G(A)))) = \{O_1,O_2,\ldots,O_p\}.$$

The orbits  $O_1, O_2, \ldots, O_p$  in the orbital partition are such that if  $i \in M$  and  $j \in N$ , then i and j are not in the same orbit. We can then refer to these orbits as *variable* orbits and *constraint* orbits. In orbital branching, we are concerned only with the variable orbits.

There are several software packages that can compute the automorphism groups required to perform orbital branching. The program nauty [13], by McKay, has been shown to be quite effective [4], and we use nauty in our orbital branching implementation.

The complexity of computing the automorphism group of a graph is not known to be polynomial time. However, nauty was able to compute the symmetry groups of our problems very quickly, generally faster than solving an LP at a given node. One explanation for this phenomenon is that the running time of nauty's backtracking algorithm is correlated to the size of the symmetry group being computed. For example, computing the automorphism group of the clique on 2000 nodes takes 85 seconds, while graphs of comparable size with little or no symmetry require fractions of a second. The orbital branching procedure quickly reduces the symmetry group of the child subproblems, so explicitly recomputing the group by calling nauty is computational very feasible. In the table of results presented in the Appendix, we state explicitly the time required in computing automorphism groups by nauty.

### 4.2 Branching Rules

The orbital branching rule introduced in §3 leaves significant freedom in choosing the orbit on which to base the partitioning. In this section, we discuss mechanisms for deciding on which orbit to branch. As input to the branching decision, we are given a fractional solution  $\hat{x}$  and orbits  $O_1, O_2, \ldots O_p$  (consisting of all currently free variables) of the orbital partitioning  $\mathcal{O}(\mathcal{G}(A(F_0^a, F_1^a)))$  for the subproblem at node a. Output of the branching decision is an index  $j^*$  of an orbit on which to base the orbital branching. We tested six different branching rules.

Rule 1: Branch Largest: The first rule chooses to branch on the largest orbit  $O_{j*}$ :

$$j^* \in \arg\max_{j \in \{1, \dots p\}} |O_j|.$$

Rule 2: Branch Largest LP Solution: The second rule branches on the orbit  $O_{j^*}$  whose variables have the largest total solution value in the fractional solution  $\hat{x}$ :

$$j^* \in \arg \max_{j \in \{1, \dots p\}} \hat{x}(O_j).$$

Rule 3: Strong Branching: The third rule is a strong branching rule. For each orbit j, two tentative child nodes are created and their bounds  $z_j^+$  and  $z_j^-$  are computed by solving the resulting linear programs. The orbit  $j^*$  for which the product of the change in linear program bounds is largest is used for branching:

$$j^* \in \arg\max_{j \in \{1,\dots p\}} (|e^T \hat{x} - z_j^+|) (|e^T \hat{x} - z_j^-|).$$

Note that if one of the potential child nodes in the strong branching procedure would be pruned, either by bound or by infeasibility, then the bounds on the variables may be fixed to their values on the alternate child node. We refer to this as *strong branching fixing*, and in the computational results in the Appendix, we report the number of variables fixed in this manner. As discussed at the end of §3.1, variables fixed by strong branching fixing may result in additional variables being fixed by orbital fixing.

Rule 4: Break Symmetry Left: This rule is similar to strong branching, but instead of fixing a variable and computing the change in objective value bounds, we fix a variable and compute the change in the size of the symmetry group. Specifically, for each orbit j, we compute the size of the symmetry group in the resulting left branch if orbit j (including variable index  $i_j$ ) was chosen for branching, and we branch on the orbit that reduces the symmetry by as much as possible:

$$j^* \in \arg\min_{j \in \{1,\dots p\}} (|\mathcal{G}(A(F_1^a \cup \{i_j\}, F_0^a))|).$$

Rule 5: Keep Symmetry Left: This branching rule is the same as Rule 4, except that we branch on the orbit for which the size of the child's symmetry group would remain the largest:

$$j^* \in \arg\max_{j \in \{1,\dots p\}} (|\mathcal{G}(A(F_1^a \cup \{i_j\}, F_0^a))|)$$

Rule 6: Branch Max Product Left: This rule attempts to combine the fact that we would like to branch on a large orbit at the current level and also keep a large orbit at the second level on which to base the branching dichotomy. For each orbit  $O_1, O_2, \ldots, O_p$ , the orbits  $P_1^j, P_2^j, \ldots, P_q^j$  of the symmetry group  $\mathcal{G}(A(F_1^a \cup \{i_j\}, F_0^a))$  of the left child node are computed for some variable index  $i_j \in O_j$ . We then choose to branch on the orbit  $j^*$  for which the product of the orbit size and the largest orbit of the child subproblem is largest:

$$j^* \in \arg\max_{j \in \{1, \dots, p\}} \left( |O_j| (\max_{k \in \{1, \dots, q\}} |P_k^j|) \right).$$

### 5 Computational Experiments

In this section, we give empirical evidence of the effectiveness of orbital branching, we investigate the impact of choosing the orbit on which branching is based, and we demonstrate the positive effect of orbital fixing. The computations are based on the instances whose characteristics are given in Table 1. The instances beginning with cod are used to compute maximum cardinality binary error correcting codes [8], the instances whose names begin with cov are covering designs [15], the instance f5 is the "football pool problem" on five matches [6], and the instances sts are the well-known Steiner-triple systems [5]. The cov formulations have been strengthened with a number of Schöenheim inequalities, as derived by Margot [12]. All instances, save for f5, are available from Margot's web site: http://wpweb2.tepper.cmu.edu/fmargot/lpsym.html.

The computations were run on machines with AMD Opteron processors clocked at 1.8GHz and having 2GB of RAM. The COIN-OR software Clp was used to solve the linear programs at nodes of the branch and bound tree. All code was compiled with the GNU family of compilers using the flags -03 -m32. For each instance, the (known) optimal solution value was set to aid pruning and reduce the "random" impact of finding a feasible solution in the search. Nodes were searched in a best-first fashion. When the size of the maximum orbit in the orbital partitioning is less than or equal to two, nearly all of the symmetry in the problem has been eliminated by the branching procedure, and there is little use to perform orbital branching. In this case,

| Name    | Variables |  |  |
|---------|-----------|--|--|
| cod83   | 256       |  |  |
| cod93   | 512       |  |  |
| cod105  | 1024      |  |  |
| cov1053 | 252       |  |  |
| cov1054 | 2252      |  |  |
| cov1075 | 120       |  |  |
| cov1076 | 120       |  |  |
| cov954  | 126       |  |  |
| f5      | 243       |  |  |
| sts27   | 27        |  |  |
| sts45   | 45        |  |  |

Table 1: Symmetric Integer Programs

we use MINTO's default branching strategy. The CPU time was limited in all cases to four hours.

In order to succinctly present the results, we use performance profiles of Dolan and Moré [3]. A performance profile is a relative measure of the effectiveness of one solution method in relation to a group of solution methods on a fixed set of problem instances. A performance profile for a solution method m is essentially a plot of the probability that the performance of m (measured in this case with CPU time) on a given instance in the test suite is within a factor of  $\beta$  of the best method for that instance.

Figure 1 shows the results of an experiment designed to compare the performance of the six different orbital branching rules introduced in §4.2. In this experiment, both reduced cost fixing and orbital fixing were used. A complete table showing the number of nodes, CPU time, CPU time computing automorphism groups, the number of variables fixed by reduced cost fixing, orbital fixing, and strong branching fixing, and the deepest tree level at which orbital branching was performed is shown in the Appendix.

A somewhat surprising result from the results depicted in Figure 1 is that the most effective branching method was Rule 5, the method that keeps the symmetry group size large on the left branch. (This method gives the "highest" line in Figure 1). The second most effective branching rule appears to be the rule that tries to reduce the group size by as much as possible. While these methods may not prove to be the most robust on a richer suite of difficult instances, one conclusion that we feel safe in making from this experiment is that considering the impact on the symmetry of the child node of the current branching decision is important. Another important observation is that for specific instances, the choice of orbit on which to branch can have a huge impact on performance. For example, for the instance cov1054, branching rules 4 and 5 both reduce the number of child nodes to 11, while other mechanisms that do not consider the impact of the branching decision on the symmetry of the child nodes cannot solve the problem in four hours of computing time.

The second experiment was aimed at measuring the impact of performing orbital fixing, as introduced in §3.1. Using branching rule 5, each instance in Table 1 was run both with and without orbital fixing. Figure 2 shows a performance profile comparing the results in the two cases. The results shows that orbital fixing has a significant positive impact.

The final comparison we make here is between orbital branching (with keep-symmetry-left branching), the isomorphism pruning algorithm of Margot, and the commercial solver CPLEX version 10.1, which has features for symmetry detection and handling. Table 2 summarizes the results of the comparison. The results for isomorphism pruning are taken directly from the paper of Margot using the most sophisticated of his branching rules "BC4" [11]. The paper [11] does not report results on sts27 or f5. The CPLEX results were obtained on an Intel Pentium 4 CPU clocked at 2.40GHz. Since the results were obtained on three different computer architectures and each used a different LP solver for the child subproblems, the CPU times should be interpreted appropriately.

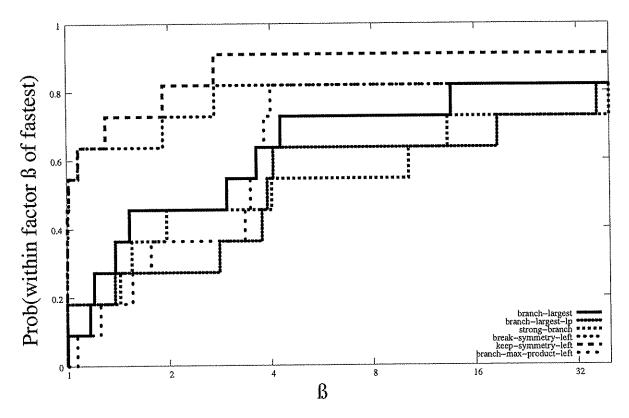

Figure 1: Performance Profile of Branching Rules

| sts45    | 3302              | 24317 | 31                  | 513         | 24          | 51078   |

Table 2: Comparison of Orbital Branching, Isomorphism Pruning, and CPLEX v10.1

The results show that the number of subproblems evaluated by orbital branching is smaller than isomorphism pruning in three cases, and in nearly all cases, the number of nodes is comparable. For the instance cov1076, which is not solved by orbital branching, a large majority of the CPU time is spent computing symmetry groups at each node. In a variant of orbital branching that uses a symmetry group that is smaller but much more efficient to compute (and which space prohibits us from describing in detail here), cov1076 can be solved in 679 seconds and 14465 nodes. Since in any optimal solution to the Steiner triple systems, more than 2/3 of the variables will be set to 1, orbital branching would be much more efficient if all variables were complemented, or equivalently if the orbital branching dichotomy (2) was replaced by its complement. Margot [11] also makes a similar observation, and his results are based on using the complemented instances, which may account for the large gap in performance of the two methods on sts45. We are currently instrumenting our code to deal with instances for which the number of ones in an optimal solution is larger than 1/2. Orbital branching proves to be faster than CPLEX in six cases, while in all cases the number of evaluated nodes is remarkably smaller.

#### 6 Conclusions

In this extended abstract, we presented a simple way to capture and exploit the symmetry of an integer program when branching. We showed through a suite of experiments that the new method, orbital branching, outperforms state-of-the-art solvers when a high degree of symmetry is present. In terms of reducing the size of the search tree, orbital branching seems to be of comparable quality to the isomorphism pruning method of Margot [11]. Further, we feel that the simplicity and flexibility of orbital branching make it an attractive candidate for further study. Continuing research includes techniques for further reducing the number of isomorphic nodes that are evaluated and on developing branching mechanisms that combine the child bound improvement and change in symmetry in a meaningful way.

### Acknowledgments

The authors would like to thank Kurt Anstreicher and François Margot for inspiring and insightful comments on this work. In particular, the name *orbital branching* was suggested by Kurt. Author Linderoth would like to acknowledge support from the US National Science Foundation (NSF) under grant DMI-0522796, by the US Department of Energy under grant DE-FG02-05ER25694, and by IBM, through the faculty partnership program.
